Abstract. We apply general variational techniques to the problem of the counterion distribution around highly charged objects where strong condensation of counterions takes place. Within a field-theoretic formulation using a fluctuating electrostatic potential, the concept of surface-charge renormalization is recovered within a simple one-parameter variational procedure. As a test, we reproduce the Poisson-Boltzmann surface potential for a single charge planar surface both in the weak-charge and strong-charge regime. We then apply our techniques to non-planar geometries where closed-form solutions of the non-linear Poisson-Boltzmann equation are not available. In the cylindrical case, the Manning charge renormalization result is obtained in the limit of vanishing salt concentration. However, for intermediate salt concentrations a slow crossover to the non-charge-renormalized regime (at high salt) is found with a quasi-power-law behavior which helps to understand conflicting experimental and theoretical results for the electrostatic persistence length of polyelectrolytes. In the spherical geometry charge renormalization is only found at intermediate salt concentrations.

1 Introduction

The behavior of charged systems has attracted renewed interest in the last few years[1]. One of the topics of interest is centered around the effects of multi-valent counterions, in which case correlations between ions become important and mean-field type theories break down. In such situations it is known experimentally and theoretically that equally charged bodies can attract each other. But even for monovalent ions and moderately to highly charged surfaces many open questions remain: In such situations the coupling parameter (which measures to which extent corrections to the mean-field or saddle-point solution are important) is not very high, but the surface potential can exceed thermal energy by far such that non-linear effects become important. The complication in this case is that the mean-field or Poisson-Boltzmann equation is a non-linear differential equation which in the presence of salt ions can be solved in closed form only in the planar geometry[2]. In the cylindrical and spherical geometry a number of different approximations have been proposed, which all more or less agree on the fact that counterions condense in the vicinity of the charged surface such as to reduce its effective surface charge[3,4]. The original Manning condensation argument states that the effective charge of a charged cylinder is maintained at a constant level of one charge per Bjerrum length[5]. The prescriptions for calculating the effective charge are numerous and

so are the predictions for the precise value of the effective charge as a function of external parameters such as salt, temperature, pH and so on[6,7,8].

In this paper we show how to approach the problem using a field-theoretic formulation of a variational theory, within which the effective surface charge is treated as a variational parameter. There are in principle two different approaches, one is based on the standard density functional theory, within which the counterion distribution is variationally determined. This approach is clumsy for more complicated geometries and in principle is difficult to generalize such as to include strong-coupling (i.e. deviations from mean-field) effects. We therefore developed an alternative approach based on an exact field-theoretic formulation using the fluctuating imaginary electric potential. The surface charge is used as a variational parameter and the variational field-theoretic action is Gaussian. This is probably the most unambiguous definition of the renormalized or effective surface charge, since no additional assumptions (other than that the variational Hamiltonian is Gaussian) is used. As a trivial byproduct, the effective interaction between charges is at large distance of the Debye-Hückel type with renormalized effective charges. Our scheme in principle allows to go beyond mean-field, but we do not pursue such studies in this paper. As we show in the appendix, the standard Gibbs variational principle can be reformulated as a perturbative variational scheme which can be systematically improved

by a perturbation series (which we also leave as a problem for the future). We test our approach for the planar charged wall, for which we essentially exactly reproduce the Poisson-Boltzmann result. We then tackle the charged cylinder. The effective cylinder charge interpolates continuously between the unrenormalized limit (at high salt concentrations) and the Manning charge-renormalized limit (at low salt concentrations), in agreement with previous results[7]. However, this crossover occurs for fully charged polyelectrolytes over 4 orders of magnitude of the salt concentration, and therefore it is important to take this slow crossover into account. For the controversial debate on the electrostatic persistence length it means that the standard Odijk-Skolnick-Fixman result[9,10,11], obtained on the linear (Debye-Hückel) level, is modified by the salt dependent effective polymer charge, which changes the salt dependency from $\ell_{\text{OSF}} \sim \kappa^{-2}$ to $\ell_{\text{OSF}} \sim \kappa^{-1.4}$, closer to experimental values[12]. For the charged sphere the resultant behavior is different: Here charge renormalization takes place only at intermediate salt concentrations and both for high and low salt concentrations the standard Debye-Hückel potential with unrenormalized charges is valid[6]. Our method can be easily generalized to more complicated geometries and situations.

2 The model

The partition function of a system consisting of N_+ positively charged and N_- negatively charged ions of the same valency q , interacting with an arbitrary charge distribution $\sigma(\mathbf{r})$, can be written as

$$\mathcal{Z} = \frac{1}{N_+!} \prod_{j=1}^{N_+} \left[\int \frac{d\mathbf{r}_j^+}{\lambda_t^3} \Omega(\mathbf{r}_j^+) \right] \frac{1}{N_-!} \prod_{j=1}^{N_-} \left[\int \frac{d\mathbf{r}_j^-}{\lambda_t^3} \Omega(\mathbf{r}_j^-) \right] \exp \left\{ -\frac{\ell_B}{2} \int d\mathbf{r} d\mathbf{r}' [q\hat{\rho}_+(\mathbf{r}) - q\hat{\rho}_-(\mathbf{r}) + \sigma(\mathbf{r})] v(\mathbf{r} - \mathbf{r}') \right. \\ \left. [q\hat{\rho}_+(\mathbf{r}') - q\hat{\rho}_-(\mathbf{r}') + \sigma(\mathbf{r}')] + \frac{q^2 \ell_B (N_+ + N_-)}{2} v(0) \right\} \quad (1)$$

The pair potential $v(\mathbf{r})$ denotes the Coulomb interaction, $v(\mathbf{r}) = 1/r$, but the first part of our discussion is rather general and independent of the specific form of $v(\mathbf{r})$. The self-energy term in Eq.(1), proportional to $q^2 \ell_B v(0)/2$, simply subtracts the diagonal term in the double integral. It will be later shown to renormalize the chemical potential (or fugacity) in a rather trivial way. The Bjerrum length $\ell_B = e^2/4\pi\epsilon k_B T$ is the distance at which two unit charges interact with thermal energy $k_B T$. The length λ_t is the thermal wavelength, which results from integrating out kinetic degrees of freedom, the precise value of which is unimportant. The function $\Omega(\mathbf{r})$ takes into account the presence of hard walls and restricts the positions of ions to an appropriate region in space, as will become more clear when we consider explicit examples in the following sections. The counterion density operators are

$$\hat{\rho}_+(\mathbf{r}) = \sum_{j=1}^{N_+} \delta(\mathbf{r} - \mathbf{r}_j^+)$$

for positively charged ions with a similar expression for the negative ions. At this point, there is not much one can do with the partition function, mainly because the density operators $\hat{\rho}_+$ and $\hat{\rho}_-$ enter in a quadratic fashion. The main step in deriving a field theory consists in introducing a unit operator which couples to the density operator $\hat{\rho}_+$,

$$1 = \int \mathcal{D}\rho_+ \delta(\rho_+ - \hat{\rho}_+) \\ = \int \mathcal{D}\rho_+ \mathcal{D}\psi_+ \exp \left\{ i \int d\mathbf{r} \psi_+(\mathbf{r}) [\rho_+(\mathbf{r}) - \hat{\rho}_+(\mathbf{r})] \right\} \quad (2)$$

(and a similar expression for the density of negative ions), where we used the integral representation of the delta function. This unit operator can be introduced into the partition function. Once introduced, it allows us to replace density operators $\hat{\rho}_+(\mathbf{r})$ and $\hat{\rho}_-(\mathbf{r})$ by the corresponding fluctuating density fields $\rho_+(\mathbf{r})$ and $\rho_-(\mathbf{r})$ and the configurational integrals over the ion positions can be performed. As a result, the partition function now reads

$$Z = \int \mathcal{D}\rho_+ \mathcal{D}\rho_- \mathcal{D}\psi_+ \mathcal{D}\psi_- \exp \left\{ -\frac{\ell_B}{2} \int d\mathbf{r} d\mathbf{r}' [q\rho_+(\mathbf{r}) - q\rho_-(\mathbf{r}) + \sigma(\mathbf{r})] v(\mathbf{r} - \mathbf{r}') \right. \\ \left. [q\rho_+(\mathbf{r}') - q\rho_-(\mathbf{r}') + \sigma(\mathbf{r}')] \right. \\ \left. + i \int d\mathbf{r} [\psi_+(\mathbf{r})\rho_+(\mathbf{r}) + \psi_-(\mathbf{r})\rho_-(\mathbf{r})] \right\} \\ \frac{1}{N_+!} \left[e^{q^2 \ell_B v(0)/2} \int \frac{d\mathbf{r}}{\lambda_t^3} \Omega(\mathbf{r}) e^{-i\psi_+(\mathbf{r})} \right]^{N_+} \\ \frac{1}{N_-!} \left[e^{q^2 \ell_B v(0)/2} \int \frac{d\mathbf{r}}{\lambda_t^3} \Omega(\mathbf{r}) e^{-i\psi_-(\mathbf{r})} \right]^{N_-}. \quad (3)$$

The partition function becomes simpler upon transformation to the grand-canonical ensemble according to

$$Z_\lambda = \sum_{N_+, N_- = 0}^{\infty} \lambda_0^{N_+ + N_-} Z \quad (4)$$

where λ_0 is the bare fugacity which is related to the particle chemical potential μ by $\lambda_0 = e^\mu$. We assume here that the chemical potential of plus and minus ions is the same. Using the definition of the exponential function, $e^x = \sum_{N=0}^{\infty} x^N/N!$, the grand-canonical partition function can be written as

$$Z_\lambda = \int \mathcal{D}\rho_+ \mathcal{D}\rho_- \mathcal{D}\psi_+ \mathcal{D}\psi_- \exp \{ -H[\rho_+, \rho_-, \psi_+, \psi_-] \} \quad (5)$$

with the field-theoretic action given by

$$H[\rho_+, \rho_-, \psi_+, \psi_-] = \\ \frac{\ell_B}{2} \int d\mathbf{r} d\mathbf{r}' [q\rho_+(\mathbf{r}) - q\rho_-(\mathbf{r}) + \sigma(\mathbf{r})] v(\mathbf{r} - \mathbf{r}') \\ [q\rho_+(\mathbf{r}') - q\rho_-(\mathbf{r}') + \sigma(\mathbf{r}')] \\ - i \int d\mathbf{r} [\psi_+(\mathbf{r})\rho_+(\mathbf{r}) + \psi_-(\mathbf{r})\rho_-(\mathbf{r})] \\ - \lambda \int d\mathbf{r} \Omega(\mathbf{r}) [e^{-i\psi_+(\mathbf{r})} + e^{-i\psi_-(\mathbf{r})}] \quad (6)$$

where we defined a rescaled fugacity as $\lambda = \lambda_0 e^{q^2 \ell_B v(0)/2} / \lambda_t^3$. As follows from the definition of the grand-canonical partition function, Eq.(4), the expectation value of the total particle number is given by

$$\langle N_+ + N_- \rangle = \lambda_0 \frac{\partial \ln Z_\lambda}{\partial \lambda_0} = \lambda \frac{\partial \ln Z_\lambda}{\partial \lambda} = \lambda \int d\mathbf{r} \Omega(\mathbf{r}) \langle e^{-\imath \psi_+(\mathbf{r})} + e^{-\imath \psi_-(\mathbf{r})} \rangle. \quad (7)$$

As can be seen, the expectation value of the particle number, $\langle N \rangle$, is independent of any multiplicative factor of the fugacity. The standard way of saying this is that the chemical potential is only defined up to a constant.

2.1 Density description

One type of approximations starts by eliminating the fluctuating fields ψ_+ and ψ_- from the problem. The simplest way of doing this is to replace the functional integral over these fields by the value of the integrand at the extremum or optimal value. The saddle point equations which determine the optimal values of the fluctuating fields, ψ_+^{SP} and ψ_-^{SP} , are given by

$$\frac{\delta H[\rho_+, \rho_-, \psi_+, \psi_-]}{\delta \psi_+(\mathbf{r})} = 0 \quad (8)$$

and with a similar equation for ψ_- . Using H as defined in Eq.(6), the solutions are

$$\psi_+^{SP}(\mathbf{r}) = \imath \ln(\rho_+(\mathbf{r})/\lambda) \quad (9)$$

(and a similar solution for ψ_-) which, upon insertion into the Hamiltonian Eq.(6), leads to the saddle-point Hamiltonian

$$\begin{aligned} H_\lambda[\rho_+, \rho_-, \psi_+^{SP}, \psi_-^{SP}] = & \frac{\ell_B}{2} \int d\mathbf{r} d\mathbf{r}' [q\rho_+(\mathbf{r}) - q\rho_-(\mathbf{r}) + \sigma(\mathbf{r})] v(\mathbf{r} - \mathbf{r}') \\ & [q\rho_+(\mathbf{r}') - q\rho_-(\mathbf{r}') + \sigma(\mathbf{r}')] \\ & + \int d\mathbf{r} \rho_+(\mathbf{r}) (\ln[\rho_+(\mathbf{r})/\lambda] - 1) \\ & + \int d\mathbf{r} \rho_-(\mathbf{r}) (\ln[\rho_-(\mathbf{r})/\lambda] - 1). \end{aligned} \quad (10)$$

This expression is the starting point for local density functional theory[13]. The extremum of Hamiltonian Eq.(10), determined by the equation

$$\frac{\delta H[\rho_+, \rho_-, \psi_+^{SP}, \psi_-^{SP}]}{\delta \rho_+(\mathbf{r})} = 0 \quad (11)$$

(and with a similar equation for ρ_-), is the mean-field or Poisson-Boltzmann density distribution. As is well-known, the mean-field equation (11) can be solved in closed form only for a few cases, and for more complicated situations one has to rely on additional approximations. One popular way of doing this is to minimize the Hamiltonian

Eq.(10) for a restricted functional form of the ion distribution, for example a box distribution. In the appendix A1 we show how this can be done for a planar charged wall (where comparison with the closed-form mean-field solution is possible). The drawback of box models is that the ion distribution is discontinuous and thus rather artificial and for more complicated charge distributions the box geometry becomes complicated. Another, more basic drawback of the density functional Eq.(10) is that correlation effects are not included on the local level. Non-local terms can in principle be taken into account by expanding around the saddle-point in Eq.(9), but the resulting functional is complicated. In the next section we show that a variational approach is more useful when applied in the potential description.

2.2 Potential description

A more powerful variational formulation is possible by choosing a description in terms of the fluctuating potentials ψ_+ and ψ_- . The starting point is the observation that the integral over the density fields ρ_+ and ρ_- in Eq. (5) can be performed exactly. Introducing the new field $\phi(\mathbf{r}) = [\psi_+(\mathbf{r}) - \psi_-(\mathbf{r})]/2$, the partition function can be written exactly as

$$Z_\lambda = \int \frac{\mathcal{D}\phi}{Z_v} \exp \{-H[\phi]\} \quad (12)$$

with

$$H[\phi] = \int d\mathbf{r} \left\{ \frac{[\nabla \phi(\mathbf{r})]^2}{8\pi \ell_B q^2} + \frac{\imath \sigma(\mathbf{r}) \phi(\mathbf{r})}{q} - 2\lambda \Omega(\mathbf{r}) \cos \phi(\mathbf{r}) \right\} \quad (13)$$

where we used the inverse of the Coulomb potential $v^{-1}(\mathbf{r}) = -\nabla^2 \delta(\mathbf{r})/4\pi$. The symbol Z_v denotes the determinant of the Gaussian integral

$$Z_v = \int \mathcal{D}\phi \exp \left\{ -\frac{1}{2q^2 \ell_B} \int d\mathbf{r} d\mathbf{r}' \phi(\mathbf{r}) v^{-1}(\mathbf{r} - \mathbf{r}') \phi(\mathbf{r}') \right\} \quad (14)$$

and is a measure of the free energy of vacuum fluctuations.

Next, we rescale all lengths by the Gouy-Chapman length $\mu = 1/(2\pi q \ell_B \sigma_s)$ according to $\mathbf{r} = \mu \tilde{\mathbf{r}}$, where σ_s denotes the surface charge density of the charged object under consideration. We obtain the modified partition function

$$Z_\lambda = \int \frac{\mathcal{D}\phi}{Z_v} \exp \left\{ -\tilde{H}[\phi]/\Xi \right\} \quad (15)$$

with the rescaled action

$$\tilde{H}[\phi] = \int \frac{d\tilde{\mathbf{r}}}{2\pi} \left[\frac{1}{4} (\nabla \phi(\tilde{\mathbf{r}}))^2 + \imath \phi(\tilde{\mathbf{r}}) \tilde{\sigma}(\tilde{\mathbf{r}}) - \frac{\Lambda \tilde{\Omega}(\tilde{\mathbf{r}}) \cos \phi(\tilde{\mathbf{r}})}{2} \right] \quad (16)$$

where we used the rescaled charge distribution $\tilde{\sigma}(\mathbf{r}/\mu) = \mu \sigma(\mathbf{r})/\sigma_s$ and ion exclusion function $\tilde{\Omega}(\mathbf{r}/\mu) = \Omega(\mathbf{r})$. The rescaled fugacity Λ is defined by

$$\Lambda = 8\pi \lambda \mu^3 \Xi = \frac{2\lambda}{\pi \sigma_s^2 \ell_B} \quad (17)$$

and is determined by the normalization condition (in the case of fixed particle number)

$$\langle N_+ + N_- \rangle = \Lambda \frac{\partial \ln Z_\Lambda}{\partial \Lambda} = \frac{\Lambda}{4\pi\Xi} \int d\tilde{\mathbf{r}} \tilde{\Omega}(\tilde{\mathbf{r}}) \langle \cos \phi(\tilde{\mathbf{r}}) \rangle. \quad (18)$$

As one can see, there are two parameters left in the field-theoretic formulation, namely the coupling parameter

$$\Xi = 2\pi\ell_B^2 \sigma_s q^3, \quad (19)$$

which measures to which extent deviations from the saddle-point are important, and the ion fugacity Λ . Infinitely far from any charged object the potential is constant and the concentration of minus and plus ions is equal and given by

$$c_s = \frac{N_+}{V} = \frac{N_-}{V} = \frac{\Lambda}{8\pi\Xi\mu^3} \langle \cos \phi \rangle \quad (20)$$

which, using the definition of the screening length, $\kappa^{-1} = (8\pi q^2 \ell_B c_s)^{-1/2}$ and the Gouy Chapman length can be rewritten as

$$\kappa^2 \mu^2 = \tilde{\kappa}^2 = \Lambda \langle \cos \phi \rangle. \quad (21)$$

The rescaled fugacity Λ thus measures the ratio between the screening length and the Gouy-Chapman length: For $\tilde{\kappa} \gg 1$ the screening by salt is dominant, non-linear effects are unimportant and Debye-Hückel theory is valid, for $\tilde{\kappa} \ll 1$ on the other hand non-linear effects are important and Debye-Hückel theory fails. It is the latter case where our variational theory becomes important.

3 Variational Theory

The action Eq.(16) is too complicated to be solved exactly. Previously, perturbative theories have been proposed for the weak-coupling (small Ξ) regime in terms of a loop-expansion around the saddle-point solution (which corresponds to the solution of the non-linear Poisson-Boltzmann equation)[14] and for the strong-coupling (large Ξ) regime in terms of a virial expansion[15,16,17]. Both expansions are of limited usefulness because of their bad convergence properties as one moves into the intermediate regime between the two asymptotic limits[18]. It is this point where variational theories come in as a robust means to obtain reliable, useful results.

The standard Gibbs variational procedure consists in minimizing the following variational free energy

$$\mathcal{F}_{Gibbs} = \mathcal{F}_0 - \langle \tilde{H}_0 - \tilde{H} \rangle_0 / \Xi \quad (22)$$

with respect to the variational parameters included in the variational Hamiltonian $\tilde{H}_0$. As discussed in detail in Appendix B the Gibbs variational principle is equivalent to the first-order perturbational variation on the observable which is conjugate to the variational parameter. The perturbational variation scheme can be systematically improved by going to higher order, the Gibbs variation cannot. Since we stay at the first-order level throughout this

paper, we will use the Gibbs variational notation, though one should keep in mind that this can be interpreted as the first order result of a perturbational variational calculation.

3.1 Most general Gaussian variation

The most general, yet exactly tractable variational Hamiltonian, is a Gaussian one

$$\tilde{H}_0[\phi] = \frac{1}{2} \int_{\mathbf{r}, \mathbf{r}'} [\phi(\mathbf{r}) - \imath\phi_0(\mathbf{r})] v_0^{-1}(\mathbf{r}, \mathbf{r}') [\phi(\mathbf{r}') - \imath\phi_0(\mathbf{r}')] \quad (23)$$

where the Gaussian kernel v_0^{-1} and the mean potential ϕ_0 are variational parameters. The variational free energy according to Eq. (22) reads

$$\begin{aligned} \mathcal{F}_{Gibbs} = & -\frac{1}{2} \text{Tr} \log v_0 - \int_{\mathbf{r}} \frac{(\nabla \phi_0)^2}{8\pi\Xi} \\ & + \int_{\mathbf{r}, \mathbf{r}'} \delta(\mathbf{r} - \mathbf{r}') \frac{\nabla_{\mathbf{r}} \nabla_{\mathbf{r}'} v_0(\mathbf{r}, \mathbf{r}')}{8\pi\Xi} \\ & - \int_{\mathbf{r}} \frac{\tilde{\sigma}(\mathbf{r}) \phi_0(\mathbf{r})}{2\pi\Xi} \\ & - \frac{\Lambda}{4\pi\Xi} \int_{\mathbf{r}} \tilde{\Omega} e^{-\Xi v_0(\mathbf{r}, \mathbf{r})/2} \cosh(\phi_0). \end{aligned} \quad (24)$$

The variational equations are given by $\delta \mathcal{F}_{Gibbs} / \delta \phi_0(\mathbf{r}) = 0$ and $\delta \mathcal{F}_{Gibbs} / \delta v_0^{-1}(\mathbf{r}, \mathbf{r}') = 0$ and read

$$\frac{\nabla^2 \phi_0}{4\pi} = \frac{\tilde{\sigma}}{2\pi} + \frac{\Lambda}{4\pi} \Omega e^{-\Xi v_0(\mathbf{r}, \mathbf{r})/2} \sinh \phi_0 \quad (25)$$

$$\begin{aligned} & - \frac{\nabla^2 v_0(\mathbf{r}, \mathbf{r}')}{4\pi\Xi} + \frac{\Lambda}{4\pi} e^{-\Xi v_0(\mathbf{r}, \mathbf{r})/2} \cosh \phi_0 v_0(\mathbf{r}, \mathbf{r}') \\ & = \delta(\mathbf{r} - \mathbf{r}') \end{aligned} \quad (26)$$

These self-consistent equations are quite complicated even for the simplest charge distribution. In the following we will devise a simpler, one-parameter variational scheme which will lead -as a byproduct- to a very simple and clear definition of the renormalized or effective charge of an object.

3.2 Variational Charge Renormalization

As we will show in the following, non-linear effects are captured in an essentially exact way already by a much simpler variational form, which as the only variational parameter contains a charge-renormalization factor. The variational Hamiltonian reads

$$\tilde{H}_0[\phi] = \int \frac{d\tilde{\mathbf{r}}}{2\pi} \left[\frac{1}{4} (\nabla \phi(\tilde{\mathbf{r}}))^2 + \imath \eta(\tilde{\mathbf{r}}) \phi(\tilde{\mathbf{r}}) \tilde{\sigma}(\tilde{\mathbf{r}}) + \frac{\tilde{\kappa}^2 \phi^2(\tilde{\mathbf{r}})}{4} \right] \quad (27)$$

where the variational function $\eta(\mathbf{r})$ multiplies the charge distribution and therefore corresponds to a spatially dependent charge renormalization factor. The Hamiltonian

is quadratic in the fluctuating field and therefore all expectation values can be calculated by using Green's function formalism. Also, the geometry-dependent factor $\Omega(\mathbf{r})$ is for the present formulation omitted and the salt concentration dependent term proportional to $\tilde{\kappa}^2$ has the same strength throughout the space. This is certainly a simplification, which however allows to use a simple translationally invariant Green's function (future elaborations should probe variational forms with a spatially dependent mass term). Using the Debye-Hückel potential

$$v_{\text{DH}}(\mathbf{r}) = \frac{e^{-\tilde{\kappa}r}}{r} \quad (28)$$

and the potential distribution

$$\phi_0(\mathbf{r}) = \frac{1}{2\pi} \int_{\mathbf{r}'} \eta(\mathbf{r}') \tilde{\sigma}(\mathbf{r}') v_{\text{DH}}(\mathbf{r} - \mathbf{r}') \quad (29)$$

the variational Hamiltonian Eq.(27) can be rewritten as

$$\begin{aligned} \tilde{H}_0[\phi] &= \frac{1}{2} \int_{\mathbf{r}, \mathbf{r}'} [\phi(\mathbf{r}) + \imath \phi_0(\mathbf{r})] v_{\text{DH}}^{-1}(\mathbf{r}, \mathbf{r}') [\phi(\mathbf{r}') + \imath \phi_0(\mathbf{r}')] \\ &+ \frac{1}{4\pi} \int_{\mathbf{r}} \eta(\mathbf{r}) \tilde{\sigma}(\mathbf{r}) \phi_0(\mathbf{r}). \end{aligned} \quad (30)$$

The variational free energy according to Eq.(22) is easily calculated and reads

$$\begin{aligned} \mathcal{F}_{\text{Gibbs}} &= \mathcal{F}_{\text{DH}} + \frac{1}{4\pi\Xi} \int_{\mathbf{r}} (2 - \eta(\mathbf{r})) \tilde{\sigma}(\mathbf{r}) \phi_0(\mathbf{r}) \quad (31) \\ &+ \frac{\tilde{\kappa}^2}{8\pi\Xi} \int_{\mathbf{r}} [\phi_0^2(\mathbf{r}) - \Xi v_{\text{DH}}(0)] \\ &- \frac{\tilde{\kappa}^2}{4\pi\Xi} \int_{\mathbf{r}} \tilde{\Omega}(\mathbf{r}) \cosh[\phi_0(\mathbf{r})] \end{aligned}$$

where we used the short-hand notation

$$\begin{aligned} \mathcal{F}_{\text{DH}} &= -\ln \int \mathcal{D}\phi \, e^{-\int_{\mathbf{r}, \mathbf{r}'} \phi(\mathbf{r}) v_{\text{DH}}^{-1}(\mathbf{r} - \mathbf{r}') \phi(\mathbf{r}') / 2\Xi} \\ &= -\frac{1}{2} \int \frac{d^3 q}{(2\pi)^3} \log(\mathbf{q}^2 + \tilde{\kappa}^2) \end{aligned} \quad (32)$$

and fixed the fugacity Λ according to Eq.(21). The variational equation follows by taking a functional derivative of the free energy with respect to the charge renormalization function, $\delta\mathcal{F}_{\text{Gibbs}}/\delta\eta(\mathbf{r}) = 0$, and reads after a few algebraic manipulations

$$\begin{aligned} \int_{\mathbf{r}} (1 - \eta(\mathbf{r})) \tilde{\sigma}(\mathbf{r}) \phi_0(\mathbf{r}) &= \\ \frac{\tilde{\kappa}^2}{2} \int_{\mathbf{r}} \phi_0(\mathbf{r}) \left(\tilde{\Omega}(\mathbf{r}) \sinh[\phi_0(\mathbf{r})] - \phi_0(\mathbf{r}) \right). \end{aligned} \quad (33)$$

This integral equation is to be solved by a suitably chosen function $\eta(\mathbf{r})$. Since in this paper we will be only concerned with situation where translational invariance holds, we will in the following section specialize the variational approach to the homogeneous case.

3.3 Homogeneous variational approach

The homogeneous variational approach is obtained by choosing a charge renormalization which is uniform in space, i.e. $\eta(\mathbf{r}) = \eta_0$. We redefine the bare potential as

$$\phi_0(\mathbf{r}) = \frac{1}{2\pi} \int_{\mathbf{r}'} \tilde{\sigma}(\mathbf{r}') v_{\text{DH}}(\mathbf{r} - \mathbf{r}') \quad (34)$$

and the Hamiltonian can be rewritten as

$$\begin{aligned} \tilde{H}_0[\phi] &= \frac{1}{2} \int_{\mathbf{r}, \mathbf{r}'} [\phi(\mathbf{r}) + \imath \eta_0 \phi_0(\mathbf{r})] v_{\text{DH}}^{-1}(\mathbf{r}, \mathbf{r}') [\phi(\mathbf{r}') + \imath \eta_0 \phi_0(\mathbf{r}')] \\ &+ \frac{\eta_0^2}{4\pi} \int_{\mathbf{r}} \tilde{\sigma}(\mathbf{r}) \phi_0(\mathbf{r}). \end{aligned} \quad (35)$$

The variational free energy according to Eq.(22) reads

$$\begin{aligned} \mathcal{F}_{\text{Gibbs}} &= \mathcal{F}_{\text{DH}} + \frac{1}{4\pi\Xi} \int_{\mathbf{r}} (2 - \eta_0) \eta_0 \tilde{\sigma}(\mathbf{r}) \phi_0(\mathbf{r}) \quad (36) \\ &+ \frac{\tilde{\kappa}^2}{8\pi\Xi} \int_{\mathbf{r}} [\eta_0^2 \phi_0^2(\mathbf{r}) - \Xi v_{\text{DH}}(0)] \\ &- \frac{\tilde{\kappa}^2}{4\pi\Xi} \int_{\mathbf{r}} \tilde{\Omega}(\mathbf{r}) \cosh[\eta_0 \phi_0(\mathbf{r})] \end{aligned}$$

The variational equation follows by taking a derivative with respect to the charge renormalization factor, $\partial\mathcal{F}_{\text{Gibbs}}/\partial\eta_0 = 0$, and is given by

$$\begin{aligned} 2(1 - \eta_0) \int_{\mathbf{r}} \tilde{\sigma}(\mathbf{r}) \phi_0(\mathbf{r}) \quad (37) \\ = \tilde{\kappa}^2 \int_{\mathbf{r}} \phi_0(\mathbf{r}) \left(\tilde{\Omega}(\mathbf{r}) \sinh[\eta_0 \phi_0(\mathbf{r})] - \eta_0 \phi_0(\mathbf{r}) \right). \end{aligned}$$

In the following we will solve this self-consistent equation for the charge-renormalization factor η_0 in the planar, cylindrical, and spherical geometries.

3.3.1 Planar case

For the calculation of the uniformly charged planar wall we assume that salt is present on both sides of the wall, the geometry factor therefore equals unity $\tilde{\Omega}(\mathbf{r}) = 1$ (it is an easy exercise to generalize the calculation to the case where salt is present only on one side of the charged wall). With the bare charge distribution $\sigma(\mathbf{r}) = \sigma_s \delta(z)$ the rescaled charge distribution becomes $\tilde{\sigma}(\tilde{\mathbf{r}}) = \delta(\tilde{z})$. The bare potential is according to Eq.(34) given by $\phi_0(\tilde{z}) = e^{-\tilde{\kappa}\tilde{z}}/\tilde{\kappa}$. The integrals in Eq.(37) can all be performed exactly, and the resulting equation becomes

$$1 - \frac{\eta_0}{2} - \frac{\tilde{\kappa}^2}{\eta_0} (\cosh[\eta_0/\tilde{\kappa}] - 1) = 0. \quad (38)$$

In the limit $\tilde{\kappa} \gg 1$ the solution is

$$\eta_0 \simeq 1 - \frac{1}{24\tilde{\kappa}^2} \quad (39)$$

and therefore only weak charge-regulation takes place, as expected for a weakly charged surface or high salt concentrations. In the opposite limit of a highly charged surface or at low salt concentrations, for $\tilde{\kappa} \ll 1$, the solution is

$$\eta_0 \simeq -\tilde{\kappa} \ln(\tilde{\kappa}). \quad (40)$$

These results can be directly compared with the Poisson-Boltzmann results derived explicitly in Appendix A2. The quantity one wants to compare is the surface potential, since this is conjugate to the surface charge density, i.e. the variational parameter, and one can reinterpret the Gibbs variational principle as a first-order perturbational variation on the expectation value of the surface potential (as is explained in more detail in Appendix B). Within our scheme, the surface potential is defined by

$$\psi_0 = \eta_0 \phi_0(\tilde{z} = 0)$$

and is given in units of $k_B T$ and valency q . For the planar case, we obtain $\psi_0 = \eta_0/\tilde{\kappa}$, and therefore find for the surface potential $\eta_0/\tilde{\kappa} = 1/\tilde{\kappa}$ at high salt ($\tilde{\kappa} \gg 1$) and $\eta_0/\tilde{\kappa} = -\ln(\tilde{\kappa})$ at low salt ($\tilde{\kappa} \ll 1$). These are the surface potentials one obtains from the full non-linear Poisson-Boltzmann theory (except a factor of two for the low-salt case). This shows that our variational procedure captures non-linear effects accurately and justifies to consider more complicated geometries, where the Poisson-Boltzmann equation can only be solved numerically.

3.3.2 Cylindrical case

We assume a charged cylinder with radius R and linear charge density τ . The surface charge density follows as $\sigma_s = \tau/(2\pi R)$. Defining the Gouy-Chapman length (like in the planar case) as $\mu = 1/(2\pi q\sigma_s)$, we obtain $\mu = R/(q\tau\ell_B)$. The rescaled cylinder radius, $\tilde{R} = R/\mu = q\tau\ell_B$ is thus equal to the Manning parameter[5]: For $\tilde{R} > 1$ one expects counterions to be bound to the cylinder even in the limit of vanishing salt concentration, for $\tilde{R} < 1$ no counterions stay bound in that limit. In the following, we assume the cylinder to be penetrable for ions, the geometry function is $\tilde{\Omega}(\tilde{r}) = 1$ for all values of $\tilde{r}$. Using cylindrical coordinates, the potential ϕ_0 as defined in Eq.(34) satisfies the differential equation

$$-\frac{1}{\tilde{r}} \frac{\partial}{\partial \tilde{r}} \tilde{r} \frac{\partial}{\partial \tilde{r}} \phi_0(\tilde{r}) + 2\delta(\tilde{r} - \tilde{R}) + \tilde{\kappa}^2 \phi_0(\tilde{r}) = 0$$

with the boundary conditions $\phi_0(\tilde{R} - 0) = \phi_0(\tilde{R} + 0)$ and $\phi'_0(\tilde{R} + 0) - \phi'_0(\tilde{R} - 0) = 2$. The complete solution is constructed from the two solutions of the homogeneous differential equation, $\phi_0(\tilde{r}) = K_0(\tilde{\kappa}\tilde{r})$ and $\phi_0(\tilde{r}) = I_0(\tilde{\kappa}\tilde{r})$, and reads

$$\phi_0(\tilde{r}) = 2\tilde{R}I_0(\tilde{\kappa}\tilde{R})K_0(\tilde{\kappa}\tilde{r}) \quad (41)$$

for $\tilde{r} > \tilde{R}$ and

$$\phi_0(\tilde{r}) = 2\tilde{R}K_0(\tilde{\kappa}\tilde{R})I_0(\tilde{\kappa}\tilde{r}) \quad (42)$$

for $\tilde{r} < \tilde{R}$. The solution of the integral equation (37) can be easily obtained graphically by calculating η_0 as a function of $\tilde{\kappa}\tilde{R}$ and $\eta_0/\tilde{\kappa}$ via numerical integration followed by a parametric plot. In Fig. 1a we show the renormalization factor η_0 as a function of the Manning parameter $\tilde{R}$ for fixed values of the rescaled inverse screening length $\kappa R = 5, 1, 0.2, 0.01$ (thin solid lines from top to bottom). The thick solid line denotes the Manning limit

$$\eta_0 = 1/\tilde{R} = 1/(\tau\ell_B q) \quad (43)$$

which is very slowly approached as the salt concentration decreases[7]. Indeed, an asymptotic analysis of the self-consistent equation (37) with the cylinder potential Eqs. (41,42) gives for $\kappa R \ll 1$

$$\eta_0 \simeq \frac{1}{\tilde{R}} \left(1 + \frac{\ln \tilde{R}}{2 \ln(1/\kappa R)} \right) \quad (44)$$

which shows that the approach to the Manning limit is logarithmically slow. In the unrescaled units, the effective cylinder charge density is

$$\tau_{\text{eff}} = \tau\eta_0 \simeq \frac{1}{\ell_B q} \left(1 + \frac{\ln \tau\ell_B q}{2 \ln(1/\kappa R)} \right) \quad (45)$$

In Fig.1b we show the data for η_0 for fixed Manning parameter $\tilde{R} = 3$ (which roughly corresponds to a fully charged vinyl-based polyelectrolyte with a distance of 0.254 nm between charges along the backbone) as a function of κR together with the asymptotic prediction Eq.(44) as a broken line in a semi-logarithmic plot and in Fig.1c as a function of $-1/\ln(\kappa R)$. It is seen that the asymptotic law is valid for low salt concentrations satisfying $\kappa R < 0.1$. For large salt concentrations, asymptotic analysis predicts that the charge-renormalization vanishes according to

$$\eta_0 \simeq 1 - \frac{1}{24\tilde{\kappa}^2} \quad (46)$$

(identical to the result for the planar case) which is shown in Fig.1b as a dotted line.

3.3.3 Nonlinear electrostatic persistence length

The electrostatic contribution to the bending rigidity has been calculated on the linear level[9,10] but also on the non-linear level using the full Poisson-Boltzmann equation for a bent cylinder[19,20]. Here we re-address the relevance of non-linear effects for the persistence length of highly charged polyelectrolytes. In Fig.1d we plot the charge renormalization factor on double logarithmic scales. Over roughly a decade in κR , which corresponds to two decades in the salt concentration, the charge renormalization factor can be approximately described by a power law $\eta_0 \sim \kappa^\alpha$ with $\alpha \approx 0.3$ (shown as a solid line). This range of salt concentrations is quite relevant for experiments[12], since it has been reported that the experimentally measured salt-concentration dependence of the persistence length

Fig. 1. a) Charge renormalization factor η_0 for a charged cylinder of radius R as a function of the Manning parameter $\tilde{R} = q\ell_B\tau$ for fixed values of the rescaled inverse screening length $\kappa R = 5, 1, 0.2, 0.01$ (thin solid lines from top to bottom). The thick solid line denotes the Manning limit Eq.(43). b-d) Results for fixed Manning parameter $\tilde{R} = 3$ as a function of the rescaled radius compared with the asymptotic low-salt prediction Eq.(44) (broken line) and the asymptotic high-salt prediction Eq.(46) (dotted line). The solid line in d) corresponds to the power-law $\eta_0 \sim \kappa^{0.3}$.

deviates from the Odijk-Skolnick-Fixman prediction, according to which

$$\ell_{\text{OSF}} = \frac{\ell_B \tau^2}{4\kappa\beta} \quad (47)$$

with $\beta = 2$ [9,10]. Replacing the bare line charge density τ in Eq.(47) by the effective charge density

$$\tau_{\text{eff}} = \eta_0 \tau \sim \kappa^\alpha \tau \quad (48)$$

(which is permissible since to leading order in an expansion for large bending radii modifications of the charge renormalization due to polymer bending are irrelevant) one obtains a modified exponent $\beta = 2 - 2\alpha \approx 1.4$ which is closer to the experimentally measured exponents[12]. Other effects that have been shown to reduce the exponent β are relevant for weakly charge chains which are crumpled at small length scales[11,21,22,23] although recent simulations using linear Debye-Hückel potentials[24, 25] as well as general Gaussian variational calculations[26] tend to confirm the original Odijk-Skolnick-Fixman prediction with $\beta = 2$. It might therefore turn out that the

true explanation for the discrepancy between experimental and theoretical predictions for the electrostatic persistence length is due to non-linear effects which had been neglected in most theoretical treatments but are of course omnipresent in experiments. Needless to say, we expect modification of a whole number of other scaling relations for polyelectrolytes which depend on the line charge density τ .

3.3.4 Spherical Case

We now treat a sphere of charge Z and radius R , leading to a surface charge density $\sigma_s = Z/(4\pi R^2)$ and Gouy-Chapman length $\mu = 1/(2\pi q\ell_B\sigma_s)$. The rescaled radius is given by $\tilde{R} = R/\mu = q\ell_B Z/(2R)$.

Using spherical coordinates, the potential ϕ_0 as defined in Eq.(34) satisfies the differential equation

$$-\frac{1}{\tilde{r}^2} \frac{\partial}{\partial \tilde{r}} \tilde{r}^2 \frac{\partial}{\partial \tilde{r}} \phi_0(\tilde{r}) + 2\delta(\tilde{r} - \tilde{R}) + \tilde{\kappa}^2 \phi_0(\tilde{r}) = 0$$

with the boundary conditions $\phi_0(\tilde{R}-0) = \phi_0(\tilde{R}+0)$ and $\phi'_0(\tilde{R}+0) - \phi'_0(\tilde{R}-0) = 2$. The two solutions of the homogeneous differential equation are $\phi_0(\tilde{r}) = e^{\tilde{\kappa}\tilde{r}}/\tilde{r}$ and $\phi_0(\tilde{r}) = e^{-\tilde{\kappa}\tilde{r}}/\tilde{r}$, from which we obtain the solutions

$$\phi_0(\tilde{r}) = 2\tilde{R} \sinh(\tilde{\kappa}\tilde{R}) e^{-\tilde{\kappa}\tilde{r}} / (\tilde{\kappa}\tilde{r}) \quad (49)$$

for $\tilde{r} > \tilde{R}$ and

$$\phi_0(\tilde{r}) = 2\tilde{R} e^{-\tilde{\kappa}\tilde{R}} \sinh(\tilde{\kappa}\tilde{r}) / (\tilde{\kappa}\tilde{r}) \quad (50)$$

for $\tilde{r} < \tilde{R}$ where we have again assumed that salt ions are present everywhere, i.e. $\tilde{\Omega}(\tilde{r}) = 1$ throughout space.

In Fig.2a we show parametric plots of the charge renormalization factor for $\kappa R = 100, 10, 1, 0.4$ (from top to bottom) and in Fig.2b for $\kappa R = 0.4, 0.1, 0.01, 0.001$ (from bottom to top). In contrast to the cylindrical case, charge renormalization is most pronounced at intermediate salt concentrations corresponding to a screening length which roughly equals the sphere radius[6]. For large salt concentrations, asymptotic analysis predicts that the charge renormalization vanishes according to

$$\eta_0 \simeq 1 - \frac{1}{24\tilde{\kappa}^2} \quad (51)$$

in agreement with the planar and cylindrical geometries. For low salt concentrations, an asymptotic analysis of the self-consistent equation (37) with the spherical potential Eqs. (49,50) gives for $\kappa R \ll 1$

$$\eta_0 \simeq \frac{1}{2\tilde{R}} \ln \left(\frac{1}{\tilde{R}\tilde{\kappa}^2} \right). \quad (52)$$

In unrescaled units this leads to an effective sphere charge

$$Z_{\text{eff}} = \eta_0 Z \simeq \frac{R}{q\ell_B} \ln \left(\frac{q\ell_B Z}{R^3 \kappa^2} \right) \quad (53)$$

which only depends very weakly on the bare sphere charge (in agreement with previous qualitative arguments[4]). In Fig.2c we compare data for a sphere with rescaled radius $\tilde{R} = R/\mu = 10$ with the asymptotic low-salt prediction Eq.(52) (broken line) and the high-salt prediction Eq.(51) (dotted line). Note that the asymptotic low-salt prediction is only valid in a finite salt-concentration limit: for very low salt concentration, the counterions are entropically driven away from the sphere and the bare charge is recovered. This might be detectable in light-scattering experiments on de-salted charged-colloid suspensions.

4 Conclusions

We have introduced the framework for a general variational technique which allows to capture non-linear effects of counterion distributions around highly charged objects in an essentially exact way. The scheme builds on the field-theoretic formulation of fluctuating counterions and uses the effective surface charge as a variational

Fig. 2. Results for the charge renormalization factor η_0 for a sphere for rescaled inverse screening lengths a) $\kappa R = 100, 10, 1, 0.4$ (from top to bottom) and b) for $\kappa R = 0.4, 0.1, 0.01, 0.001$ (from bottom to top). c) Charge renormalization factor for fixed $\tilde{R} = R/\mu = 10$ together with the asymptotic prediction Eq.(52) (broken line) and the prediction Eq.(51) (dotted line).

parameter. Since we use a Gaussian variational Hamiltonian, the resulting interactions between charged particles are of the Debye-Hückel type, but with the bare charges replaced by effective ones. This scheme is thus very close to the treatment by Kjellander et al.[27], where a similar procedure was used within an integral-equation scheme. We show how in principle to systematically improve the leading term results by using perturbational variational methods. We tested our approach for the planar geometry, where comparison with the analytical solution of the non-linear Poisson-Boltzmann equation is possible, and then presented a detailed analysis of the cylindrical and spherical case. In the future, we will apply these methods to the interaction between charged bodies (including the experimentally relevant case of a charged cylinder adsorbing on a charge plane[28]), soft (fluctuating) charged polymers and membranes. We also plan to investigate higher-order perturbation variational terms which will allow to include effects at high coupling parameter Ξ where deviations from the mean-field like behavior are important.

A Appendix: Charged planar wall

In this section we will treat the single charged wall immersed in a salt solution using a box model and using the Poisson Boltzmann equation.

A.1 Box model

The mean-field Hamiltonian in terms of the ionic densities, Eq.(10), can be used as a starting point for a simplified variational treatment using a box model, where the true ionic density distribution is replaced by a step profile. The fugacity can be fixed by the ionic density in the bulk where we assume the electrostatic interactions to vanish. Minimization Eq.(10) with respect to the density of plus ions yields

$$\frac{\delta H}{\delta \rho_+} = \ln(\rho_+/\lambda) = 0 \quad (54)$$

and thus $\rho_+ = \lambda$. We conclude that the fugacity is given by the ionic density in the bulk reservoir, i.e. $\lambda = \rho_+^b$.

As a box model we assume a negatively charged planar wall of surface charge density σ_s which is neutralized by a uniformly charged box of width d . We assume that the wall charge is neutralized by an excess of positive ions, i.e. the density of negative ions stays constant. The electric field distribution thus is

$$\frac{eE}{k_B T} = 4\pi\ell_B \sigma_s \frac{d-z}{d} \quad (55)$$

and the electrostatic energy (per unit area and per $k_B T$) follows as

$$\begin{aligned} U &= \frac{\varepsilon}{2k_B T} \int dz E^2 = \frac{1}{8\pi\ell_B} \int dz \left(\frac{eE}{k_B T} \right)^2 \\ &= 2\pi\ell_B \sigma_s^2 d/3. \end{aligned} \quad (56)$$

The excess entropy of the layer of condensed counterions is

$$-S = d \left\{ \left(\rho_+^b + \frac{\sigma}{qd} \right) \left(\log \left[1 + \frac{\sigma_s}{qd\rho_+^b} \right] - 1 \right) + \rho_+^b \right\}. \quad (57)$$

Minimization of the free energy $F = U - S$ leads for high salt concentrations (for $\kappa\mu = \tilde{\kappa} \gg 1$) to the optimal layer thickness

$$d^2 \simeq \frac{3}{4\pi\ell_B q^2 \rho_+^b} = 6\kappa^{-2} \quad (58)$$

which is proportional to the screening length κ^{-1} (as expected) and for low salt concentrations (for $\kappa\mu \ll 1$) to

$$d \simeq \frac{3}{2\pi\ell_B q \sigma_s} = 3\mu \quad (59)$$

and thus to a layer thickness which differs from the Gouy Chapman length μ only by a numerical factor. The surface free energies are given by

$$F \simeq \frac{2\sqrt{6}\sigma_s}{3q\kappa\mu} \quad (60)$$

for high salt and

$$F \simeq \frac{2\sigma_s}{q} \log \left(\frac{1}{\kappa\mu} \right). \quad (61)$$

for low salt.

A.2 Poisson-Boltzmann equation

The Poisson-Boltzmann equation follows from minimizing the Hamiltonian Eq.(16) with respect to the potential distribution. Defining the real electrostatic potential $\psi = \imath\phi$ the saddle point equation can be written as

$$\psi''(z) + 2\delta(z) - \tilde{\kappa}^2 \sinh \psi = 0. \quad (62)$$

The solution is

$$\psi(z) = 2 \log \left(\frac{1 - \gamma e^{-\kappa z}}{1 + \gamma e^{-\kappa z}} \right) \quad (63)$$

where the constant γ is determined by the boundary conditions. In the case when the charged wall is impenetrable to ions, the boundary condition is $\psi'(0) = -2$, which leads to the equation $\gamma^2 - 1 = 2\gamma\tilde{\kappa}$. For low salt concentrations the constant follows as $\gamma \simeq -1 + \kappa$ and the surface potential is given by

$$\psi_0 \simeq 2 \ln(1/\tilde{\kappa}). \quad (64)$$

The surface free energy in this limit is $F = \psi_0 \sigma_s / (2q) = (\sigma_s/q) \ln(1/\tilde{\kappa})$ and thus differs from the box-model calculation only by a prefactor. For high salt concentrations the constant is $\gamma = -1/(2\tilde{\kappa})$ and the surface potential is

$$\psi_0 \simeq 2/\kappa. \quad (65)$$

The surface free energy is $F = \sigma_s/(\tilde{\kappa}q)$ and is also reproduced by the box-model calculation. In the case when the surface is penetrable to ions, as is used in our variational calculations, the surface potential in the low salt limit is not modified to leading order,

$$\psi_0 \simeq 2 \ln(1/\tilde{\kappa}), \quad (66)$$

while in the high salt limit one obtains

$$\psi_0 \simeq 1/\kappa. \quad (67)$$

B Appendix: Connection between the Gibbs Variational Principle and Perturbative Variation

Let us start by considering the free energy

$$\mathcal{F} = -\ln \int \mathcal{D}\phi e^{-\mathcal{H}} \quad (68)$$

where $\mathcal{H}$ depends on the fluctuating field ϕ . We introduce a variational Hamiltonian $\mathcal{H}_0(\mathbf{x})$ which depends on the fluctuating field ϕ and on the vector $\mathbf{x}$, the components of which may act as variational parameters and/or as generating fields to calculate observables. Adding and subtracting the variational Hamiltonian to the action, the free energy can be written as

$$\mathcal{F} = -\ln \int \mathcal{D}\phi e^{-\mathcal{H}_0(\mathbf{x})} - \ln \left[\frac{\int \mathcal{D}\phi e^{-\mathcal{H}_0(\mathbf{x}) + \zeta Y}}{\int \mathcal{D}\phi e^{-\mathcal{H}_0(\mathbf{x})}} \right] \quad (69)$$

where we defined

$$Y = \mathcal{H}_0(\mathbf{x}) - \mathcal{H} \quad (70)$$

and introduced a dummy parameter ζ which is used to count orders in a perturbation series (and will eventually be set to unity). The free energy can now be expanded in cumulants as

$$\mathcal{F}_n = \mathcal{F}_0(\mathbf{x}) - \sum_{m=1}^n \frac{\zeta^m}{m!} \langle Y^m \rangle_0^C \quad (71)$$

where $\mathcal{F}_0(\mathbf{x})$ denotes the free energy of the variational Hamiltonian

$$\mathcal{F}_0(\mathbf{x}) = -\ln \int \mathcal{D}\phi e^{-\mathcal{H}_0(\mathbf{x})} \quad (72)$$

and $\langle \dots \rangle_0^C$ denotes the cumulant average with respect to the variational Hamiltonian. Clearly, the exact free energy is approached in the infinite limit of the series, i.e. $\mathcal{F} = \mathcal{F}_{n \rightarrow \infty}$. The standard perturbation technique is often slowly converging for problems of interest. Variational techniques typically perform much better. The standard Gibbs-variational technique exploits the fact that the first order perturbation result $\mathcal{F}_1$ is always larger than the true

free energy, $\mathcal{F}_1 \geq \mathcal{F}$. The approximate free energy is therefore given by minimizing $\mathcal{F}_1$ with respect to the set of variational parameters,

$$\mathcal{F}_{\text{Gibbs}} = \min_{\mathbf{x}} \mathcal{F}_1(\mathbf{x}). \quad (73)$$

However, it is not easy to systematically improve this result (since the property of the perturbative free energy to be bound by the true free energy is lost at higher order), other than by choosing a more refined variational Hamiltonian, which is often not possible. The perturbational variation, which has been introduced by Edwards for the calculation of the scaling behavior of self-avoiding polymers[29], consists in requiring the perturbative free energy of any order to be equal to the zeroth order free energy,

$$\mathcal{F}_0(\mathbf{x}) = \mathcal{F}_n(\mathbf{x}) \quad (74)$$

which is equivalent to the condition

$$\sum_{m=1}^n \frac{\zeta^m}{m!} \langle Y^m \rangle_0^C = 0. \quad (75)$$

This equation has to be solved by fixing the set of variational parameters $\mathbf{x}$. To do this, it is convenient to expand the parameters in a power series $\mathbf{x} = \sum_{i=1}^n \zeta^{i-1} \mathbf{x}^{(i)}$ and to solve Eq.(75) term by term. (If the variational parameter is not expanded in a series but Eq.(75) is solved directly, one recovers the naive perturbation result. The hope is therefore that the expansion of the variational parameters improves the convergence behavior of the series for the free energy.) One notes that the prediction for the free energy from the Gibbs variational approach, Eq.(73), and the perturbational variation, Eq.(74), are not equal, not even at the leading order. It is a priori not clear which approximation is closer to the exact free energy.

Often one is not interested in the free energy itself but in a certain observable. We define an arbitrary observable X_j as being conjugate to the field x_j according to

$$X_j = \frac{\partial \mathcal{H}_0(\mathbf{x})}{\partial x_j}. \quad (76)$$

The first few terms of the expansion of the expectation value of X_j in powers of ζ are

$$\begin{aligned} \langle X_j \rangle &= \langle X_j \rangle_0 + \zeta [\langle X_j Y \rangle_0 - \langle X_j \rangle_0 \langle Y \rangle_0] \\ &+ \frac{\zeta^2}{2} [\langle X_j Y^2 \rangle_0 - 2 \langle X_j Y \rangle_0 \langle Y \rangle_0 - \langle X_j \rangle_0 \langle Y^2 \rangle_0 + 2 \langle X_j \rangle_0 \langle Y \rangle_0^2]. \end{aligned} \quad (77)$$

As before, the perturbative variation consists of demanding that the corrections to the leading contribution of the expectation value vanish, i.e.

$$\langle X_j \rangle = \langle X_j \rangle_0, \quad (78)$$

which can be solved by adjusting one or more of the variational parameters $\mathbf{x}$.

A quite instructive connection exists between the Gibbs variational method and the perturbative variation: In the

case when the Gibbs variational parameter is the field x_j conjugate to the observable X_j , the Gibbs variational equation and the first order perturbative variation Eq.(78) are identical. This means that the higher order perturbative variational method on the expectation value can be viewed as a generalization of the Gibbs variational technique. One might hope to approximate the true free energy better, though the true free energy ceases to be a strict lower bound for the perturbational free energy expression.

Some comments are in order:

i) In principle, the calculated observable in equation (77) does not need to be conjugate to the variational parameter. In any case, it is clear that in principle the observable can be calculated to any wanted precision by taking enough terms in the perturbation-variational treatment.

ii) Several expectation values can be calculated, for which an equal number of variational parameters are needed to solve the uniform expansion condition.

v) It is not clear that equation (78) always has a solution. In that case one could try to find the best estimate to the solution.
